

# Monetary and macroprudential policy with multi-period loans\*

Michał Brzoza-Brzezina<sup>†</sup>   Paolo Gelain<sup>‡</sup>   Marcin Kolasa<sup>§</sup>

February, 2014

## Abstract

We study the implications of multi-period loans for monetary and macroprudential policy, considering several realistic modifications – variable vs. fixed loan rates, non-negativity constraint on newly granted loans, and occasionally binding collateral constraint – to an otherwise standard DSGE model with housing and financial intermediaries. In line with the literature, we find that monetary policy is less effective when contracts are multi-period, but only under fixed rate mortgages or when borrowers cannot be forced to accelerate repayment of their loans. Moreover, the probability that the collateral constraint becomes slack depends on loan maturity only for fixed rate mortgages while the probability that the non-negativity constraint becomes binding grows with loan maturity regardless of the contract type. As a result, multi-period loans not only weaken monetary and macroprudential policy, but also introduce asymmetry into their transmission.

# 1 Introduction

Empirical evidence suggests that differences in the financial sector across countries have important implications for the transmission of monetary policy.<sup>1</sup> Recent contributions focusing on the structure of housing finance (see e.g. Campbell, 2013) highlight that there is a substantial heterogeneity among industrialized countries in terms of the characteristics of residential mortgage markets. Those differences affect the way a monetary policy action transmits to the economy. Giuliadori (2005), Assenmacher-Wesche and Gerlach (2008), and Calza et al. (2013) all stress that, among several institutional characteristics of national mortgage systems, having fixed or variable mortgage rates makes the largest difference for the effects of monetary policy on house prices and real variables (e.g. residential investment, consumption, and GDP). Moreover, those studies find that the monetary policy transmission is more efficient in those countries where variable-rate mortgages are prevalent.

If the evidence is strong for monetary policy, it is much less for macroprudential policy. Cardarelli et al. (2009) stress that the role of housing demand shocks in explaining the variability of consumption is stronger in those countries where the degree of mortgage market development is higher. In their paper, a high degree of market development is associated, among other things, with high loan-to-value ratios and longer loan maturity. Those two variables turn out to be non-negligible determinants of consumption variability.<sup>2</sup>

On the theoretical ground, standard dynamic stochastic general equilibrium (DSGE) models with housing, like for instance Iacoviello (2005) and many others, typically abstract from most of – if not all of – the above features of mortgages. In particular, the most common assumptions are that contracts last for one period, they are stipulated on the basis of a variable interest rate, and the collateral constraint faced by borrowers is always binding. As a consequence, these models cannot assess the implications that the mortgage market design might have for monetary and macroprudential policies.

---

<sup>1</sup>Cecchetti (1999) and Ehrmann et al. (2003) examine the issue in a broader context than the one we are interested in. In particular, the former looks at differences in the size, concentration, and health of national banking systems, as well as in the availability of non-bank sources of finance among the European Union countries. The latter considers size, capitalization, and liquidity of banks in the Euro Area.

<sup>2</sup>Cardarelli et al. (2009) find that among the determinants they select to construct their mortgage market development index, the only one that has a strongly statistically significant association is the share of mortgage backed securities in new residential loans. Nevertheless, several other variables have a coefficient with the expected sign and t-statistics above 1. The loan-to-value ratio and loan maturity are part of the latter group. Calza et al. (2013) also consider these two variables, but they do not propose any analysis variable by variable.

In this paper we first evaluate the impact of having multi-period vs. one-period contracts on monetary and macroprudential policy in an otherwise standard DSGE model with housing and financial intermediaries. Second, we investigate whether or not fixed as opposed to variable rate mortgages can influence the nature of our results. Third, we analyze the possible interactions between loan maturity and the fact that households' collateral constraint might be only occasionally binding. Finally, given that in a multi-period framework the collateral constraint on total debt introduces the possibility for new loans to become negative – possibility that is absent by definition in the one-period contract case – we analyze the effects of imposing the realistic constraint that borrowers cannot be forced to accelerate repayment of their debt (non-negativity constraint on new loans) and its interactions with loan maturity. Based on the first two departures we contribute to some extent in an original manner to the literature, but with the last two we give an absolutely novel contribution.

In fact, papers coping with multi-period mortgages (or long-term housing finance) do exist. Articles totally unrelated to policy issues and with diversified aims are: Campbell and Cocco (2003) on optimal mortgage choice, Hurst and Stafford (2004) and Li and Yao (2007) on consumption smoothing, Chambers et al. (2009b) and Chambers et al. (2009a) on equilibrium homeownership rates, Garriga and Schlagenhaut (2009), Chatterjee and Eyigungor (2011), and Corbae and Quintin (2011) on equilibrium foreclosures, and Kydland et al. (2012) on the dynamics of residential investments.

On the policy side, theoretical contributions are all very recent and almost all of them focus on monetary policy and not on macroprudential policy. Benes and Lees (2010) investigate the implications of the existence of multi-period fixed-rate loans for the behaviour of a small open economy exposed to finance shocks and housing boom-bust cycles. Rubio (2011) studies how the proportion of fixed and variable rate mortgages affects business cycles and welfare in a DSGE model with housing. Calza et al. (2013) provide a rationale for their empirical findings by developing a DSGE model with two-period mortgage contracts, assuming that the existence of loans of different maturities reflects the distinction between variable rate and fixed rate contracts. Garriga et al. (2013) use the multi-period mortgage setup developed in Kydland et al. (2012) to analyze how monetary policy functions in such a context. Gelain et al. (2014a) also use the Kydland et al. (2012) framework to revisit the leaning-against-the-wind argument in a model where households' debt-to-income ratio dynamics is in line with the one observed in the data. All those papers conclude that conducting monetary policy in an environment where mortgage contracts are taken out at fixed

rates hampers the central bank’s ability to stabilize the economy. Our findings in this respect are in line with theirs.

The only paper dealing with the consequences for macroprudential policy of multi-period mortgages is Gelain et al. (2014b). They borrow the analytical framework of the mortgage market from Kydland et al. (2012), and extend the analysis to the macroprudential policy case.<sup>3</sup> Their setup differs from ours in two important respects. First, we specify the collateral constraint in the spirit of Iacoviello (2005), i.e. by limiting households’ debt by the value of housing, while in Kydland et al. (2012) this constraint takes into account only newly granted loans and is limited by current residential investment. Second, we are explicit in specifying our debt contracts as variable-rate fixed-principal or fixed-rate fixed-installment loans, while Kydland et al. (2012) use a parsimonious approximation to mimic fixed-installment contracts. As we demonstrate, in our framework the distinction between one and multi-period contracts is irrelevant for variable rate mortgages unless the non-negativity constraint on new loans is binding.<sup>4</sup> This is because the sequence of expected interest rates for a multi-period loan equals the series of expected interest rates for rolled-over single period loans. On the contrary, in Kydland et al. (2012) the distinction between one and multi-period loans is always relevant, also with variable rates.<sup>5</sup>

Our framework is more similar to Calza et al. (2013), with three important differences. First, we generalize the framework from two-period contracts to  $m$ -period contracts. Second, we move away from the assumption that variable rate mortgages are one-period contracts and fixed rate mortgages are equivalent to long-term contracts. In this way the mortgage type and mortgage maturity become two distinct dimensions of our analysis. Third, and most importantly, we allow – together with the budget constraint – also the collateral constraint to take into account loans granted in the past and not yet repaid. This last feature is the one that introduces the possibility for new loans to become negative.<sup>6</sup>

---

<sup>3</sup>Gelain et al. (2014b) also study how the multi-period contract setup, being able to better match the house prices and the household debt dynamics observed in the data, can reduce the importance of exogenous disturbances, like housing preference or LTV shocks, in accounting for the observed variability in those variables.

<sup>4</sup>A corollary is that monetary and macroprudential policy work the same way regardless of the fact that contracts are either single or multi-period.

<sup>5</sup>See Garriga et al. (2013) for explanation why in the Kydland et al. (2012) framework introducing multi-period loans creates a nominal rigidity which always leads monetary policy to have real effects regardless of the contract type.

<sup>6</sup>Yet another way of including nominal rigidities into housing loans is a staggered evolution of the interest rate as e.g. in Rubio (2011) – where the loan rate is a weighted average of current and past short and long

From the point of view of the policy implications, we share with Gelain et al. (2014b) the result that in the baseline model (i.e. with the permanently binding collateral constraint and without the non-negativity constraint), monetary policy is less effective under the assumption of multi-period loans, although we show that it is true under fixed-rate contracts but not under variable-rate ones, while Gelain et al. (2014b) only focus on the latter case. However, the most interesting and original results of our paper are related to the implications of the multi-period contracts when imposing the non-negativity constraint on new loans or introducing the possibility that the collateral constraint may become slack. Our main findings in those respects are as follows. As already stressed, the non-negativity constraint comes into play only when contracts are multi-period. We find that under variable rates both monetary and macroprudential policy are weakened, with stronger effects when loan maturity increases. Moreover, an asymmetry arises in the functioning of those two policies because the constraint can become binding only for shocks decreasing the value of collateralizable assets.

As for the collateral constraint, we evaluate whether the fact that it can become slack might influence the transmission mechanism of monetary and macroprudential policies and whether there is an interaction between the probability of that constraint to become non-binding and the mortgage maturity. Not surprisingly, the effects of both policies are weakened when shocks are large enough to make the constraint slack. As in the case of non-negativity constraint, the dynamics here is also asymmetric, given that the constraint binds occasionally only for shocks increasing the collateral value. In terms of the probability of becoming slack, the results are different under variable and fixed rate contracts. In the former case, there is no interaction with the maturity, i.e. the probability of the collateral constraint becoming slack is the same regardless of the contract length. In the latter, given that under fixed rates the reaction of the stock of loans becomes weaker with higher maturities, the probability for the constraint to become slack is smaller for longer maturities.

The rest of the paper is structured as follows. Sections 2 and 3 present the model and its calibration. Section 4 discusses the results. Section 5 concludes.

## 2 Model

We start from a standard medium-sized New Keynesian setup, extended to incorporate housing and credit frictions by building on Iacoviello (2005) and modified to allow for multi-rates – or Liam and Stephen (2007) – where the loan rate evolves in a Calvo-style ‘sticky’ fashion.

period loans. A key feature of our extension, particularly relevant in a multi-period contract environment, is that the collateral constraint is not assumed to hold with equality every period. Instead, borrowers' total debt burden can occasionally exceed or fall below the value of collateralizable assets.

Our model economy is populated by two types of households, housing and capital producers, goods producers, and the government authorities. Below we sketch the optimization problems facing each class of agents, focusing particularly on those that make up the key ingredients of our extension.

## 2.1 Households

To introduce credit, we distinguish between two types of households that differ in their subjective discount rates. Those relatively patient are indexed by  $P$  and make natural lenders, while the impatient group, denoted by  $I$ , are natural borrowers. The share of impatient households in population is  $\omega$ . Within each group, a representative agent  $\iota$  maximizes

$$\mathbb{E}_0 \left\{ \sum_{t=0}^{\infty} \beta_i^t \left[ \ln c_{i,t}(\iota) + A_\chi \frac{\chi_{i,t}(\iota)^{1-\sigma_\chi}}{1-\sigma_\chi} - \frac{n_{i,t}(\iota)^{1+\sigma_n}}{1+\sigma_n} \right] \right\} \quad (1)$$

for  $i = \{I, P\}$  and  $\beta_I < \beta_P$ . In the formula above,  $c_t$  is consumption,  $\chi_t$  denotes the housing stock and  $n_t$  is labor supply.

Patient households' maximization is subject to a standard budget constraint

$$\begin{aligned} P_t c_{P,t} + P_{\chi,t}(\chi_{P,t} - (1 - \delta_\chi)\chi_{P,t-1}) + P_{k,t}(k_t - (1 - \delta_k)k_{t-1}) + D_t = \\ = W_{P,t}n_{P,t}(\iota) + R_{k,t}k_{t-1} + R_{t-1}D_{t-1} + \Pi_t + T_{P,t} + \Xi_{P,t}(\iota) \end{aligned} \quad (2)$$

where  $k_t$  denotes capital,  $R_{k,t}$  is its rental rate,  $\Pi_t$  is profits from monopolistically competitive firms,  $T_{i,t}$  is lump-sum net transfers,  $P_{\chi,t}$  and  $P_{k,t}$  denote housing and physical capital prices,  $W_{i,t}$  is nominal wage,  $D_t$  stands for one-period deposits paying a risk-free rate  $R_t$  that is set by the central bank and  $\Xi_{i,t}$  is the payout from state-contingent securities traded between households of the same type and providing perfect insurance against household-specific labor income risk arising from wage stickiness.<sup>7</sup>

<sup>7</sup>The presence of these securities allows us to save on notation and drop indexing other households' allocations with  $\iota$ .

Impatient households do not accumulate physical capital nor hold any equity, and have access to  $m$ -period mortgage loans. In our baseline specification mortgages are taken out at variable interest rates and with fixed principal payments, so that each period a borrower has to pay interest on the outstanding debt at the rate set at the beginning of the period, and repay the amount of principal due. Hence, her budget constraint can be written as

$$\begin{aligned}
P_t c_{I,t} + P_{\chi,t}(\chi_{I,t} - (1 - \delta_\chi)\chi_{I,t-1}) + (R_{\chi,t-1} - 1) \sum_{j=1}^m \frac{m-j+1}{m} L_{t-j} + \frac{1}{m} \sum_{j=1}^m L_{t-j} = \\
= W_{I,t} n_{I,t}(\iota) + L_t + T_{I,t} + \Xi_{I,t}(\iota) \quad (3)
\end{aligned}$$

or more compactly

$$P_t c_{I,t} + P_{\chi,t}(\chi_{I,t} - (1 - \delta_\chi)\chi_{I,t-1}) + R_{\chi,t-1} S_{t-1} = W_{I,t} n_{I,t}(\iota) + S_t + T_{I,t} + \Xi_{I,t}(\iota) \quad (4)$$

where  $R_{\chi,t}$  is gross interest charged on loans by banks and  $S_t$  is end-of-period debt defined as

$$S_t = \sum_{j=1}^m \frac{m-j+1}{m} L_{t-j+1} \quad (5)$$

Additionally, impatient households' optimization is subject to a collateral constraint. Unless it implies  $L_t < 0$ , it is given by the following inequality

$$R_{\chi,t} S_t \leq \vartheta_t (1 - \delta_\chi) \mathbb{E}_t \{ P_{\chi,t+1} \chi_{I,t} \} \quad (6)$$

where  $\vartheta_t > 0$  denotes the target loan to value (LTV) ratio set by the macroprudential authority. Otherwise, since banks cannot force borrowers to accelerate repayment of outstanding debt, newly granted loans just dry up ( $L_t = 0$ ), which minimizes the deviations of the observed LTV ratio from that recommended by the macroprudential authority. Note that, since the housing stock owned by households must be positive, the latter case can only arise with multi-period contracts, i.e. for  $m > 1$ . As a result, similarly to Justiniano et al. (2013), our modeling setup allows for increases in the observed LTV ratio above the levels implied by bank (or macroprudential) policies during the episodes of plummeting house prices or sharp tightening of lending standards. It also provides a mechanism making the effectiveness of macroprudential policy contingent on the state of the economy and on the scale of policy interventions.

Each household supplies differentiated labor in a monopolistically competitive fashion. Nominal wages are assumed to be sticky as in the Calvo scheme. More specifically, each period only a randomly selected fraction  $1 - \theta_w$  of households can reoptimize while the remaining wages are automatically indexed to the steady state inflation.

## 2.2 Firms

There are several types of firms in our model. Perfectly competitive final goods producers aggregate intermediate goods indexed by  $\nu$  according to

$$y_t = \left[ \int_0^1 y_t(\nu)^{\frac{1}{\mu}} d\nu \right]^\mu \quad (7)$$

Intermediate goods producing firms operate in a monopolistically competitive environment and use the following production function

$$y_t(\nu) = k_{t-1}(\nu)^\alpha n_t(\nu)^{1-\alpha} \quad (8)$$

where homogenous labor input is defined as

$$n_t(\nu) = [\omega n_{I,t}(\nu)]^\gamma [(1 - \omega) n_{P,t}(\nu)]^{1-\gamma} \quad (9)$$

Intermediate firms are subject to nominal rigidities so that each period only a random fraction  $1 - \theta$  of them can reset their prices while the remaining ones adjust their prices to the steady state inflation. Since these firms are owned by patient households, they use their marginal utility to discount the future profits.

Finally, housing and capital production is undertaken by perfectly competitive firms owned by patient households. They purchase undepreciated housing and capital from the previous period and produce new stocks according to the following formulas

$$\chi_t = (1 - \delta_\chi) \chi_{t-1} + \left( 1 - \Gamma_\chi \left( \frac{i_{\chi,t}}{i_{\chi,t-1}} \right) \right) i_{\chi,t} \quad (10)$$

$$k_t = (1 - \delta_k) k_{t-1} + \left( 1 - \Gamma_k \left( \frac{i_{k,t}}{i_{k,t-1}} \right) \right) i_{k,t} \quad (11)$$

where  $i_{\chi,t}$  and  $i_{k,t}$  are final goods used for housing and capital investment while the adjust-

ment costs functions are parametrized such that  $\Gamma_j(1) = \Gamma'_j(1) = 0$  and  $\Gamma''_j(1) = \kappa_j \geq 0$  for  $j = \{\chi, k\}$ .

## 2.3 Banks

Perfectly competitive banks collect deposits from patient households and use them to extend loans to impatient households. Their problem is hence to maximize

$$\mathbb{E}_0 \left\{ \sum_{t=0}^{\infty} \beta_P^t c_{P,t}^{-1} (R_{\chi,t-1} S_{t-1} - S_t + D_t - R_{t-1} D_{t-1}) \right\} \quad (12)$$

subject to

$$D_t = S_t \quad (13)$$

## 2.4 Government

The fiscal authority follows a passive policy, purchasing a constant fraction  $g_y$  of final goods and financing its expenditures with lump sum taxes levied on households such that the government budget is balanced every period

$$P_t g_t = g_y P_t y_t = \omega T_{I,t} + (1 - \omega) T_{P,t} \quad (14)$$

where  $P_t$  is the price of final goods. The tax policy is such that the share of each type of households in the total tax burden is fixed at  $\tau_i$  for  $i = \{I, P\}$ .

The monetary authority sets the policy rate according to the standard Taylor-like rule

$$\frac{R_t}{R} = \left( \frac{R_{t-1}}{R} \right)^{\gamma_R} \left[ \left( \frac{\pi_t}{\pi} \right)^{\gamma_\pi} \left( \frac{y_t}{y} \right)^{\gamma_y} \right]^{1-\gamma_R} e^{\varepsilon_{R,t}} \quad (15)$$

where variables without time subscripts denote their steady state values and  $\varepsilon_{R,t}$  is a monetary policy shock.

The macroprudential authority actions are modeled as an exogenous autoregressive process

$$\vartheta_t = (1 - \gamma_\vartheta) \vartheta + \gamma_\vartheta \vartheta_{t-1} + \varepsilon_{\vartheta,t} \quad (16)$$

where  $\varepsilon_{\vartheta,t}$  is a macroprudential policy shock.

## 2.5 Market clearing

The model is closed with a standard set of market clearing conditions. In particular, housing market clearing implies

$$\chi_t = \omega\chi_{I,t} + (1 - \omega)\chi_{P,t} \quad (17)$$

and the aggregate resource constraint is

$$y_t = \omega c_{I,t} + (1 - \omega)c_{P,t} + i_{k,t} + i_{\chi,t} + g_t \quad (18)$$

## 2.6 Fixed rate mortgages

Our baseline specification of loan contracts assumes that they are taken out at variable interest rates. In this case, the solution to banks' problem given by (12)-(13) is very simple as it implies that the interest charged on loans  $R_{\chi,t}$  is equal to the policy rate  $R_t$  every period. Also, it follows from impatient households' budget constraint (4) that, unless the non-negativity constraint on loans is binding, there is no difference between single and multi-period loans. This is because impatient households' financial decisions can be described using only their debt  $S_t$ , without any need to refer to its maturity structure given by  $L_{t-j+1}$  for  $j = 1, \dots, m$ .

However, as documented by Campbell (2013), in many countries (and in the US in particular), the vast majority of housing loans are long-term fixed-rate mortgages, with repayments made in equal installments every period. To incorporate this type of contract into our model, impatient households' budget constraint (3) needs to be modified to

$$\begin{aligned} P_t c_t^I(\iota) + P_{\chi,t}(\chi_t^I(\iota) - (1 - \delta_\chi)\chi_{t-1}^I(\iota)) + \frac{1}{m} \sum_{j=1}^m \tilde{R}_{\chi,t-j} L_{t-j}(\iota) = \\ = W_t n_t^I(\iota) + L_t(\iota) - T_t \end{aligned} \quad (19)$$

where  $\tilde{R}_{\chi,t}$  is gross total interest cost of a loan. To ensure comparability with our baseline, the collateral constraint is specified as before, except that now the end-of-period debt is

$$S_t = \frac{1}{m} \mathbb{E}_t \left\{ \sum_{j=1}^m \tilde{R}_{\chi,t-j+1} L_{t-j+1} \Upsilon_t^j \right\} \quad (20)$$

where the discounting term is defined as

$$\Upsilon_t^j = \sum_{i=1}^{m-j+1} \frac{1}{R_t \dots R_{t+i-1}} \quad (21)$$

Hence, as in the variable-rate case, the left-hand side of the collateral constraint is the next period value of outstanding debt, defined as the expected present value of all future repayments due from time  $t + 1$  to the loan maturity date  $t + m$ . In particular, this form of the constraint ensures that the steady-state allocations do not depend on the mortgage type.

A modified problem of banks can be written as

$$\mathbb{E}_0 \left\{ \sum_{t=0}^{\infty} \beta_P^t c_{P,t}^{-1} \left( \frac{1}{m} \sum_{j=1}^m \tilde{R}_{\chi,t-j} L_{t-j} - L_t + D_t - R_{t-1} D_{t-1} \right) \right\}$$

subject to

$$D_t = \sum_{j=1}^m \frac{m-j+1}{m} L_{t-j+1}$$

It can be verified that if one abstracts away from uncertainty, i.e. in the steady state equilibrium, the solution to banks' problem is

$$\tilde{R}_{\chi} = m \frac{R-1}{1-R^{-m}}$$

which is a standard annuity formula.

### 3 Calibration and solution

We calibrate the model to US data, measuring time in quarters. The assumed parameter values are reported in Table 1.

Following the standard practice, a subset of parameters are taken from the literature or calibrated to match the long-run averages observed in the data. Households' utility is parametrized such that it implies a moderate Frisch elasticity of labor supply and a substantially stronger smoothing motive in housing compared to consumption. The discount factor of patient households is set to obtain an annualized average real interest rate of slightly

below 3%. Following Campbell and Hercowitz (2009), the relative impatience of borrowers is assigned at 0.5% quarterly. The steady state inflation rate is set to match the annual average of 2%. Physical capital is assumed to depreciate at 2% per quarter and its share in output is set to 0.3, both values being standard in the literature. The share of government purchases in output matches the long-run average of 16.5%. The steady-state LTV ratio, share of housing in utility and housing depreciation rate are calibrated to jointly match the following three long-run proportions: the debt-to-GDP ratio of 0.46, the share of residential investment in output of 4.5% and the housing-to-GDP ratio of 1.25.

While calibrating the parameters controlling the degree of heterogeneity between patient and impatient households, we follow Justiniano et al. (2013) and make sure that our choices are consistent with micro data evidence from the Survey of Consumer Finances (SCF). More specifically, we set the share of impatient households to equal the share of liquidity constrained consumers in this dataset of 61%. According to this source, a typical borrower works 8% more hours and her labor income is 36% lower compared to an average lender. We use these two statistics to pin down the share of impatient households in production and the degree of redistribution via the tax system. Such calibration also implies that the average total income of borrowers is about 40% of that of savers, which comes very close to 46% reported by the SCF.

The parameters controlling real and nominal rigidities, i.e. wage and price markups and stickiness, as well as investment adjustment costs are set at standard values assumed in the literature. Finally, the central bank rule is also parametrized in line with the original Taylor rule, except that we allow for some moderate interest rate smoothing. The degree of inertia in macroprudential policy is set at the same level as that for the monetary policy.

Due to non-linearities arising from inequality in the collateral constraint and the non-negativity restriction on newly granted loans, the model cannot be solved using standard perturbation techniques. To deal with this problem, we use the piecewise linear method developed by Guerrieri and Iacoviello (2014). This algorithm has the advantage of being applicable to models with a large number of state variables, and hence is particularly useful in our multi-period contract environment.

## 4 Results

We are now ready to show how multi-period loans work and how their presence affects the transmission of monetary and macroprudential policies. Our benchmark is the standard model with eternally binding collateral constraint and variable interest rate loans, i.e. equation (6) is assumed to hold as equality, which is a valid assumption for sufficiently small shocks. As we argued before, in this case it does not matter whether loans are single or multi-period. In particular, monetary and macroprudential policy affect the economy the same way. Our project could stop here with nothing. However, as we show below, the apparently minor but realistic deviations from this standard setup that we include in our model are sufficient to generate substantial differences between the working of single and multi-period contracts. In the remaining part of this section we show what happens to the transmission of monetary and macroprudential policy shocks if we take into account the following features of the mortgage market:

1. banks cannot force borrowers to accelerate loan repayment,
2. the collateral constraint might be slack,
3. loans are taken out at fixed interest rates.

While considering multi-period loans, we set their maturity to 20 periods, i.e. 5 years. This is enough to generate sizable differences, but, naturally, longer maturities would make our arguments even stronger. The size of shocks is chosen each time so as to obtain a clear demonstration of our main points.

### 4.1 Non-negativity constraint on new loans

Our first departure from the standard setup is imposing a non-negativity constraint on new loans, implying that banks cannot demand faster debt repayment when the observed LTV ratio exceeds the limit set by the macroprudential authority. As explained before, this modification does not change anything in the single-period setting since the collateral value is always positive. However, once loans become multi-period, debt is no longer equivalent to the flow of loans. While the former still must be positive, the collateral constraint can imply a negative flow after sufficiently strong shocks. This feature of the standard model is

highly unrealistic, since in the real world both the stock and the flow of new loans are always non-negative.

Figure 1 presents the impulse responses of GDP, inflation, debt and flow of new loans to a contractionary macroprudential policy shock, defined as a decrease in the target LTV ratio  $\vartheta_t$  by 3 percentage points. For  $m = 20$ , this shock is strong enough to push new loans into a negative region in the benchmark model (dashed line falls below -100%). When the constraint on faster debt repayment is switched on (solid line), the fall of loans is limited by the floor of -100%. As a result, debt declines by less and so does output. This difference is sizable as the contraction in output is nearly 40% smaller if the non-negativity constraint is taken into account. Hence, allowing for this constraint can substantially weaken the effects of macroprudential policy tightening.

A similar picture emerges after a monetary policy shock. Figure 2 documents monetary transmission to a big positive shock of 2 percentage points. In the unconstrained model new loans become negative again. Adding the constraint puts a floor on new loans, hence limiting the decline in debt, GDP and inflation. As a result, the effects of monetary policy tightening become weaker.

Two things should be noted. First, as already explained, this constraint makes a difference only in a multi-period loan setting and this difference is increasing in the loan maturity  $m$ . Second, it works in an asymmetric way - it becomes binding only after sufficiently strong and contractionary shocks. Hence, the combination of multi-period loans and the non-negativity constraint not only weakens the effects of monetary and macroprudential policy, but also introduces asymmetry into their transmission.

## 4.2 Occasionally binding collateral constraint

We next check how the slackness in the collateral constraint interacts with multi-period loans. As explained before, when the constraint is permanently binding and loans are taken at variable interest, their maturity does not affect policy transmission. However, in the real world this constraint should be rather thought of as not always binding - banks cannot force borrowers to take more loans just because the value of collateralizable assets increases. In particular, an increase in the target LTV ratio will boost lending when the constraint is tight and not necessarily so if its level before the intervention does not effectively limit impatient households' financial choices.

This effect is illustrated in Figure 3, which plots the responses to an easing of the LTV policy by 1.5 percentage points for variable rate multi-period contracts when occasional slackness in the collateral constraint is allowed (solid lines) or the constraint is assumed to hold with equality every period (dashed lines).<sup>8</sup> Clearly, for large enough shocks the collateral constraint stops binding, which weakens the policy transmission. The effects of policy changes also become asymmetric, since the constraint can become slack only for expansionary shocks. Similar effects can be observed for sufficiently big monetary policy shocks (not shown).

It is worth noting that, for our calibration, the magnitude of shocks for which the possible slackness in the collateral constraint becomes relevant is smaller than in the case of the non-negativity constraint on new loans. Hence, in our model that takes into account both possibilities, a policy expansion has smaller effects than a policy tightening. This is consistent with empirical evidence presented in Ravn and Sola (2004) who find that only moderate monetary tightening has real effects. Hence, our framework offers an explanation for this empirical finding that can be an alternative or complement to the standard downward nominal wage rigidity argument.

Given the focus of this paper, another interesting question is whether allowing for occasionally binding collateral constraints generates interesting interactions with loan maturity. In the baseline case of variable interest rate contracts, the answer to this question is no, for reasons similar to those discussed before. More precisely, the collateral constraint imposes a limit on total debt which, if mortgages are taken out at variable rates, does not depend on the contract length. Hence, whether it becomes slack is not affected by maturity either.

### 4.3 Fixed interest rate contracts

In the next step we change the contract type from variable to fixed interest rates, making it more consistent with mortgage market design observed in many countries. To fix our attention, we abstract for a while from the possibility of hitting the non-negativity constraint or the collateral constraint becoming slack and set the magnitude of shocks such that these additional features of our model are irrelevant.

We first apply a contractionary LTV shock and compare the impulse responses of variable (dashed lines) and fixed (solid lines) interest rates multi-period loans. As explained before, if

---

<sup>8</sup>Note that our model is parametrized such that the collateral constraint is binding in the steady state, which is also the starting point for our simulations.

the collateral constraint holds with equality and the interest rates are adjusted every period, the loan maturity does not matter, so our experiment can also be thought of as a comparison between single and multi-period loans under fixed interest rates.

As evidenced in Figure 4, this modification has very little effect. This is because the response of the interest rate to a macroprudential policy shock is very small and hence the difference between a fixed and variable interest rate mortgage insignificant. Naturally, this result comes from the fact that the central bank responds mainly to inflation, which changes very little in this scenario, and the difference between the two contract types would become bigger if we parametrized the Taylor rule such that it reacts mainly to output.

A different picture emerges when monetary policy shocks are analyzed (Figure 5). By construction, a monetary policy tightening implies an increase in the interest rate, which makes the cost of servicing the debt more expensive to impatient households, especially if mortgage interest payments are adjusted every period. In the case of fixed interest contracts, the increase in the policy rate affects only the cost of newly granted loans, making borrowers more immune to the tightening. As can be seen from the figure, the difference between fixed and variable rate mortgages is sizable and would be even larger if we assumed the average loan maturity of more than 5 years.

More generally, the presence of fixed-rate multi-period contracts will dampen (amplify) the credit market effects of shocks that spark an adjustment in the interest rate that goes in the opposite (same) direction than the response of loans. As an example, consider a standard housing preference shock, defined as a temporary increase in the weight of housing in household utility  $A_\chi$ . In a model like ours, this shock leads to an increase in credit and expansion in economic activity, to which the central banks reacts by raising the short-term interest rate. Since, holding the Taylor rule parameters fixed, monetary policy is less powerful under fixed interest mortgages, housing preference shocks will have bigger effects on the economy.

#### 4.4 Strenght of monetary and macroprudential policy transmission

TBA. Peak of impulse responses as function of maturity will come here figures:

1. monetary policy shock, flex rate, small and big negative and positive

2. monetary policy shock, fixed rate, small and big negative and positive
3. macropru policy shock, flex rate, small and big negative and positive
4. macropru policy shock, fixed rate, small and big negative and positive

## 4.5 Efficient policy frontiers

TBA. Policy frontiers for monetary and macroprudential policies will come here figures:

1. EPF for monetary policy, short and long maturity, flex rate and fixed rate
2. EPF for macropru policy, short and long maturity, flex rate and fixed rate

## 5 Conclusions

In this paper we modify an otherwise standard DSGE model with housing and financial intermediaries in order to take into account typical characteristics of residential mortgage markets – those that empirical studies have found to be relevant in many dimensions and that are largely ignored in the theoretical literature. The aim of considering those modifications, which make our model more realistic, is to evaluate to what extent they affect the transmission mechanism of both monetary and macroprudential policy, already found to be affected on the empirical ground.

The main modification we focus on is the introduction of multi-period loan contracts. With it we obtain our baseline model where contracts are stipulated with variable interest rates, households collateral constraint is assumed to be always binding, and new loans have the unrealistic feature that they might become negative for large enough shocks. Given this contrast with the evidence of our baseline model, we first impose the non-negativity constraint on new loans. Second, we allow for the possibility for the collateral constraint to be occasionally binding and we evaluate possible interactions with loan maturity. Third, we relax the assumption of variable rates and introduce fixed rates to study how they might affect our results.

In line with the empirical and theoretical literature, we find that both monetary and macroprudential policy are less effective when contracts are multi-period, but only under fixed mortgage rates. Under variable rates the distinction between one and multi-period contracts is irrelevant, i.e. both policies work the same way regardless of the loan maturity.

When we impose the non-negativity constraint, we show that it can substantially weaken the effects of both monetary and macroprudential policy tightening. Moreover, it introduces an asymmetry in the functioning of those two policies because the constraint can become binding only for contractionary shocks. Also in the case of occasionally binding collateral constraint, both policy are weakened. We show that the strength of both mechanisms depends on the maturity of loans.

All in all, we can conclude that, with our modifications, multi-period loans not only weaken monetary and macroprudential policy, but also introduce asymmetry into their transmission.

## Tables and figures

Table 1: Calibration

Parameter	Value	Description
$\beta_P$	0.993	Discount factor, patient HHs
$\beta_I$	0.988	Discount factor, impatient HHs
$\delta_\chi$	0.009	Housing stock depreciation rate
$\delta_k$	0.02	Capital stock depreciation rate
$\omega$	0.61	Share of impatient HHs in population
$\gamma$	0.5	Share of impatient HHs in production
$A_\chi$	2500	Weight on housing in utility
$\sigma_\chi$	5	Inverse of intertemporal elasticity of substitution in housing
$\sigma_n$	1	Inverse of Frisch elasticity of labor supply
$\mu_w$	1.2	Steady state wage markup
$\theta_w$	0.75	Calvo probability for wages
$\mu$	1.2	Steady state product markup
$\theta$	0.75	Calvo probability for prices
$\alpha$	0.3	Output elasticity with respect to physical capital
$\kappa_k$	5	Capital investment adjustment cost
$\kappa_\chi$	5	Housing investment adjustment cost
$g_y$	0.165	Share of government spending in output
$\tau$	-0.165	Share of taxes levied on impatient HHs
$\vartheta$	0.65	Steady state LTV ratio
$\gamma_\vartheta$	0.8	LTV smoothing in macroprudential rule
$\pi$	1.005	Steady state inflation
$\gamma_R$	0.8	Interest rate smoothing in monetary policy rule
$\gamma_\pi$	1.5	Response to inflation in monetary policy rule
$\gamma_y$	0.5	Response to output in monetary policy rule

Figure 1: Reaction to macroprudential policy under non-negativity constraint

Note: LTV shock (- 3%) without (dashed) and with (solid) the non-negativity constraint binding (20-period loans). All responses are in percent deviations from the steady state.

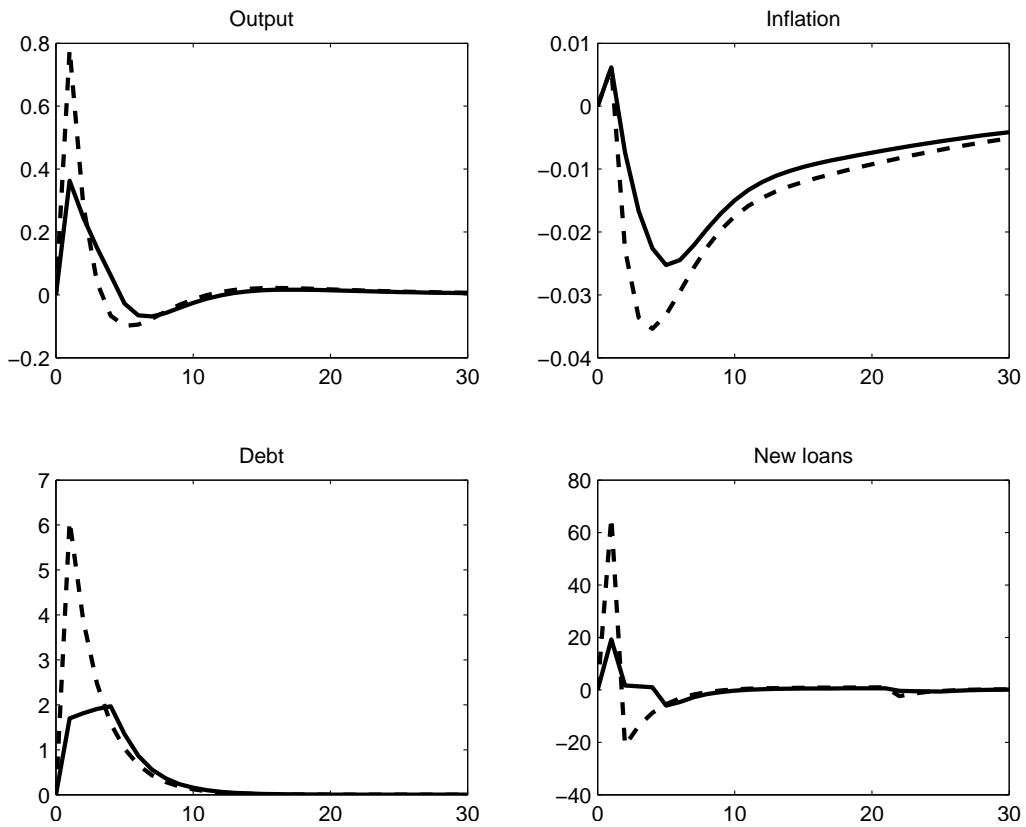

Figure 2: Reaction to monetary policy under non-negativity constraint

Note: Monetary policy shock (2%) without (dashed) and with (solid) the non-negativity constraint binding (20-period loans).  
All responses are in percent deviations from the steady state.

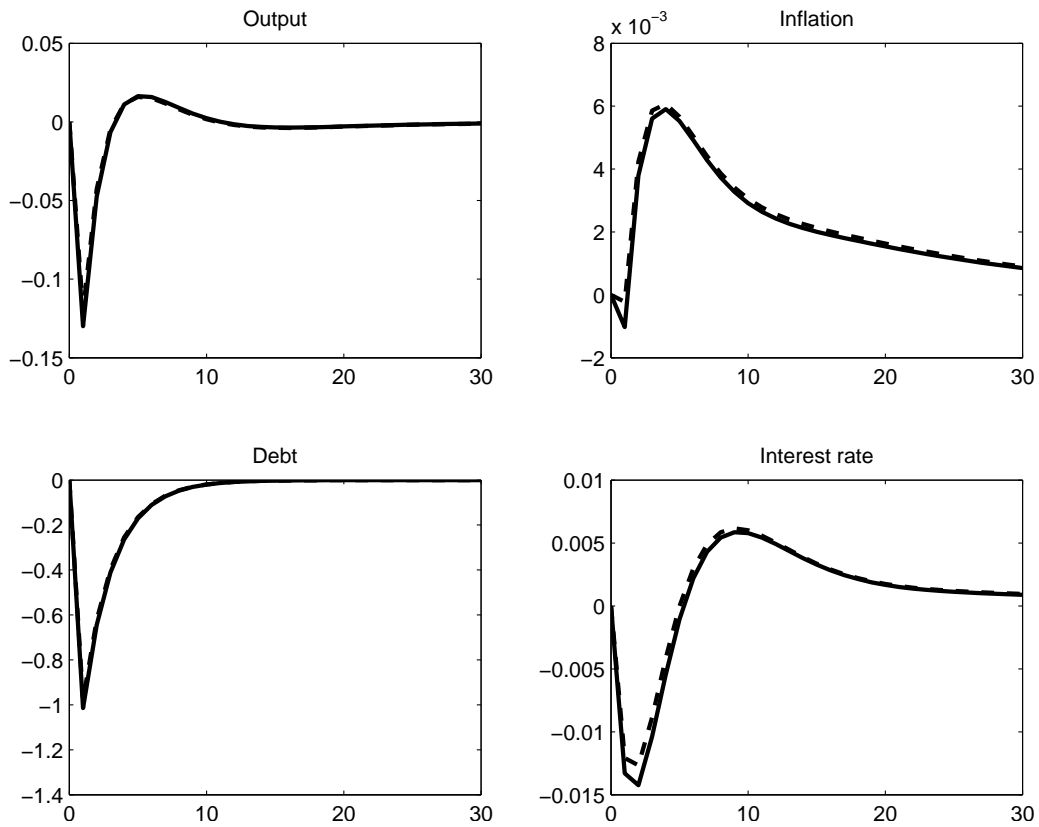

Figure 3: Reaction to macroprudential policy under occasionally binding collateral constraint

Note: LTV shock (1.5%) for occasionally (solid) and eternally (dashed) binding collateral constraints. All responses are in percent deviations from the steady state.

Figure 4: Reaction to macroprudential policy under fixed rate loans

Note: LTV shock (-0.25%) for fixed (solid) and variable (dashed) rate loans. All responses are in percent deviations from the steady state.
